## OECD SOCIAL, EMPLOYMENT AND MIGRATION WORKING PAPERS

www.oecd.org/els/workingpapers

This series is designed to make available to a wider readership selected labour market, social policy and migration studies prepared for use within the OECD. Authorship is usually collective, but principal writers are named. The papers are generally available only in their original language – English or French – with a summary in the other.

Comment on the series is welcome, and should be sent to the Directorate for Employment, Labour and Social Affairs, 2, rue André-Pascal, 75775 PARIS CEDEX 16, France.

The opinions expressed and arguments employed here are the responsibility of the author(s) and do not necessarily reflect those of the OECD.

Applications for permission to reproduce or translate all or part of this material should be made to:

#### ABSTRACT

Macro-level changes can have substantial effects on the distribution of resources at the household level. While it is possible to speculate about which groups are likely to be hardest-hit, detailed distributional studies are still largely backward-looking. This paper suggests a straight forward approach to gauge the distributional and scale implications of large output changes at an early stage. We illustrate the method with an evaluation of the impact of the 2008-2009 crisis in Germany. We take as a starting point a very detailed administrative matched employer-employee dataset to estimate labor demand and predict the effects of output shocks at a disaggregated level. The predicted employment effects are then transposed to household-level micro data, in order to analyze the incidence of rising unemployment and reduced working hours on poverty and inequality. We focus on two alternative scenarios of the labor demand adjustment process, one based on reductions in hours (intensive margin) and close to the German experience, and the other assuming extensive margin adjustments that take place through layoffs (close to the US situation). Our results suggest that the distributional and scale consequences are less severe when labor demand reacts along the intensive margin.

Key Words: Labor demand; Tax-benefit system; Crisis; Income Distribution.

JEL Classification : D58, J23, H24, H60.

#### RESUME

Les changements au niveau macroéconomique peuvent exercer des effets importants sur la répartition des ressources au niveau des ménages. Alors qu'on peut conjecturer des catégories qui risquent d'être le plus fortement touchées, les études détaillées sur la distribution des revenus sont en grande partie rétrospectives. Ce document propose une approche directe pour mesurer les implications de la répartition et l'ampleur des évolutions d'ensemble à un stade précoce. La méthode est illustrée par une évaluation de l'impact de la crise de 2008-2009 en Allemagne. On utilise comme point de départ un ensemble de données administratives employeur/employé pour estimer la demande d'emploi et prédire les effets des chocs à un niveau détaillé. Les effets attendus sur l'emploi sont ensuite transposés aux micro-données au niveau du ménage de manière à analyser l'incidence de l'augmentation du chômage et de la réduction des heures de travail sur la pauvreté et l'inégalité. . Deux scénarios sur le processus d'ajustement de la demande d'emploi sont étudiés : un scénario sur la réduction des heures de travail (marge intensive), proche de l'expérience allemande ; et un scénario qui suppose des ajustements intensifs des marges par le biais des licenciements (proche de la situation existant aux États-Unis). Les résultats laissent penser que les conséquences sur la répartition et l'ampleur du phénomène sont moins sévères quand la demande d'emploi

#### DISTRIBUTIONAL CONSEQUENCES OF LABOR DEMAND ADJUSTMENTS TO A DOWNTURN: A MODEL-BASED APPROACH WITH APPLICATION TO GERMANY 2008-09

### 1. Introduction

1. The 2008-2009 economic crisis has led to a broad discussion, both in public and academia, about which policy might be most effective at mitigating the adverse labor-market and welfare consequences of the downturn. While a large number of policy initiatives has quickly followed the onset of the economic slump, policy efforts to minimize welfare losses are seriously hampered by how little is known about the distribution of changes in employment and incomes, and about the capacity of existing redistribution systems to soften the negative impacts of job and earnings losses. In order to assess the real-time consequences of the downturn, policymakers would need real-time micro data to obtain a precise picture of the distributional distortions. While it is possible to speculate about which groups are likely to be hardesthit, detailed distributional studies are usually not available until the crisis is long over and important policy decisions have already been made.

2. In this paper, we develop a straightforward approach to gauge the distributional and fiscal implications of large output changes at an early stage. Rather than imputing income changes using reweighting techniques or similar procedures, we identify demand-side adjustments using an estimated labor demand model, and then feed them to household data, in order to assess their distributional consequences. We illustrate the method with an evaluation of the impact of the 2008-2009 crisis in Germany. More precisely, we first estimate a labor demand model based on twelve years of high-quality, micro-level administrative employer-employee data (LIAB). The model is used to predict the employment effects of output shocks observed during the current labor market downturn at a disaggregated level (by industry and for labor inputs detailed by age, skill and contract type). In a second step, we transpose the predicted labor-market changes to household-level micro data commonly used for distributional analyses (the German Socio-Economic Panel, GSOEP). Using this combined approach, we can analyze the first-round consequences of the recession for gross income changes at the household level. Employing taxbenefit simulation, we can also assess the income cushioning effects of the welfare system and quantify aggregate fiscal effects.

3. While the demand model captures total labor demand adjustment reasonably well, nothing can be inferred about the precise margin of adjustment. Yet it is likely that the type of adjustment matters for the distributional implications of the labor-market downturn. Therefore we suggest two scenarios for translating labor-demand reactions to earnings losses at the household level. The first polar case allows for adjustments at the intensive margin only (adjusting working hours per employee rather than staff levels). We will refer to this as the intensive scenario. The second polar case (extensive 1 scenario) shows what happens if the same overall adjustments in total working hours occur exclusively via layoffs (and hires). The two polar cases are stylized and intended to show the main links between margins of adjustment and distributional outcomes. Yet the first case closely corresponds to the German situation where labor-market adjustments to a sharp drop in GDP occurred almost exclusively along the intensive margin. By contrast, other countries, including the United States, saw major layoffs and substantial increases in unemployment rates (OECD, 2010). Hence our extensive scenario can be interpreted as a counterfactual of what would have happened if Germany had experienced more of a US-style labor market response to the crisis.

4. Our results show that the margin of adjustments indeed matters. Given the likely pattern of job losses among different groups of workers, adjustments at the extensive margin result in a sizable widening of the income distribution, increasing inequality and driving up the number of poor people by more than ten percent. In the intensive scenario, poverty headcounts rise by under four percent, while most inequality measures are predicted to change little. Importantly, adjustments at the intensive margin are also preferable from a fiscal point of view, at least in the short-term.

5. To the best of our knowledge, this is the first empirical study linking output changes to distributional and fiscal consequences using a detailed micro model of labor-demand responses. The approach is conceptually related to the literature on linking micro and macro models (see, e.g., Bourguignon et al. (2003), or Peichl (2009) for a survey)<sup>1</sup>. In particular, it is closer to the "top-down" approach which aims to approximate the effect of macro changes on income distribution. However, in our study, the macro level output shocks are not derived from a stylized CGE-type of model but correspond directly to the observed changes per industry for the years 2008-2009.<sup>2</sup> Hence, we ignore longer-term changes in prices and wages which are justified in the German case since wage adjustments were not a primary channel for reducing labor costs during the downturn (Collective Agreement Archive (2009), Bellmann and Gerner, 2010). Instead we focus on short-term labor demand adjustments, which are the most immediate driver of household income losses during a labor-market downturn. Our approach puts the emphasis on a model that accounts for the heterogeneity of adjustment patterns needed for distributional analyses.

6. The remainder of the paper is structured as follows. Section 2 briefly summarizes the labormarket changes in Germany since the onset of the crisis and contrasts them with the US experience. In Section 3, we lay out our empirical approach, present the data and the estimation of the labor demand model. In Section 4, we predict the first-round effect of output shocks on the demand for different labor inputs, compare them to observed labor- market trends, and analyze the distributional consequences of labor market adjustments at the household level. Finally, we derive and discuss the fiscal consequences of working-hour reductions versus layoffs. Section 5 concludes.

#### 2. The German Labor Market during the Crisis

7. The German labor market performance has received considerable attention since the onset of the 2008-2009 economic crisis. Figure 1 illustrates the unique adjustment patterns in Germany by contrasting the evolution of output and employment against those observed in the United States.

8. During the recent economic crisis, Germany suffered particularly sizable output losses of almost seven percent since GDP peaked in 2008Q1. Yet, employment levels as shown by the black solid line remained practically unchanged, suggesting an unusually low Okun's coefficient value. Nonetheless, Figure 1 shows that the crisis did have a significant effect on the German labor market. Up until 2009Q2, hours worked per employee (as well as total working hours in the economy) declined by four percent (black dashed line). Hence, on aggregate, the adjustments materialized exclusively at the intensive margin (the difference between the solid and the dashed lines). In contrast to the German situation, US employment dropped by almost five percent despite a smaller drop in GDP (grey solid line). Most of the

<sup>&</sup>lt;sup>1</sup> For distributional analyses based on these techniques and specific applications to economic crises, see Bourguignon et al. (2008), Herault (2010), Ahmed and O.Donoghue (2010), Ferreira et al. (2008) and Robilliard et al. (2008).

<sup>&</sup>lt;sup>2</sup> Note that the method that we suggest here is more general as it does not depend on observed data on actual output changes. It can also be applied as a tool for ex ante policy response analyses if one uses projections (of output changes) in order to analyze forward-looking counterfactual scenarios.

adjustment happened along the extensive margin whereas working-hour reductions along the intensive margin accounted for only around one third of the drop in total hours worked (grey dashed line).

9. The specific adjustment witnessed in Figure 1 is in part the result of possibilities and constraints induced by labor market conditions and institutions (see, e.g., Möller (2010), Eichhorst et al. (2010), OECD, 2010). In the German context, the government-supported short-time working scheme (the *Kurzarbeitergeld*) has tended to receive most of the attention. Yet, while a substantial part (around 25 percent) of working-time reductions during the crisis to date can indeed be directly attributed to this programme, other factors were more important on aggregate. The biggest reductions, accounting for more than one third of recorded changes in total hours worked, were due to opening clauses in collective agreements, which provide for temporary reductions in weekly working hours (and earnings), or to so-called "pacts for employment and competitiveness" between employers and employees. In addition, working-time accounts or "time banks", as well as substantially reduced overtime, account for about 20 percent each (Bellmann *et al.*, 2008).

Figure 1: Labor-market Adjustments: Germany vs. US

Source: OECD National Accounts database and calculations based on national and Eurostat labor market statistics. Notes: Q0 is the quarter when GDP peaked (2007Q4 for US and 2008Q1 for Germany) and each data point refers to consecutive quarters since then.

10. In our analysis, we set up a framework which is general enough to comprise both the intensive and extensive margin. This allows us to simulate two polar scenarios of adjustment, which come close to the contrasted situations depicted in Figure 1. This will be described in the next Section.

## 3. Empirical Approach

11. To study the short-term effects of a large output shock on employment and income, we derive the likely patterns of demand-side adjustments using our own labor demand estimations. We assume a .right-to-manage setting, with employment and hours chosen by the .rm. Wages are fixed in the short term and labor inputs are the only margins of adjustment for firms (capital is constant). The labor demand model is estimated on matched employer-employee data for Germany. In a second step, the demand-side model is linked to household-level data and tax/benefit simulations are conducted in order to derive the distributional consequences. Before proceeding with the distributional analysis in Section 4, this section presents details on data sources and labor demand estimations.

## 3.1. Data

12. The demand model relies on a high-quality linked employer-employee dataset (LIAB) from the Institute for Employment Research (IAB) in Nuremberg, Germany, (see Alda et al. (2005) for more information on the dataset and von Wachter and Bender (2006) for a recent application). The firm component of the LIAB is the IAB Establishment Panel (cf. Kölling (2000). The term "establishment" refers to the fact that the observation unit is the individual plant, not the firm; there can be several plants per company. The Establishment Panel is a representative stratified random sample containing annual information on establishment structures and personnel decisions for years 1993 onwards. It includes establishments with at least one worker for whom social contributions were paid, covering 16 industries and establishments from both West and East Germany. Information on employment levels and changes, the structure of staff qualification, export, investment and technological status as well as industry a¢ liation and output are used.

13. The employee data corresponds to the employment statistics of the German Federal Employment Agency (Bundesagentur für Arbeit), drawn from official records - the German employment register - which comprises all employees paying social security taxes or receiving unemployment benefits (see, e.g., Bender *et al.*, 2000). The dataset covers about 80 percent of German employees in the private sector. The entire public sector is excluded as civil servants are not observed in the social security data. Information recorded in the data includes employees histories on daily wages, age, seniority, schooling, training, occupation, employment type (full-time, part-time or irregular employment), industry and region.

14. Data from the employee history are linked with the establishment sample year-by-year using a plant identi.er. Since the unified sample for East and West Germany exists only since 1996, we focus on the period 1996-2007. We select establishments with at least 10 employees, in order to be able to identify substitution patterns between different types of workers. In total, our resulting sample consists of 37; 958 establishment-year observations. The number of establishment-years is 19; 520 in manufacturing (51 percent of the total), 5; 035 in construction (13 percent), 1; 847 in transport and communications (5 percent), 10; 956 in services (29 percent) and 600 in financial services (2 percent).

15. For the distributional analysis, we use the German Socio-Economic Panel (GSOEP), a 5 wellknown household survey. The GSOEP is a representative survey of the entire German population with about 25; 000 sample individuals living in more than 10; 000 households per cross-section (East Germany was added in 1990) (see Wagner *et al.*, 2007). For the present paper, we utilize information on labormarket status, gross wage, job type, benefits, industry, working time, household composition, age, education levels and housing costs. We use the 2008 wave, containing labor market information, in particular hours worked and wages, for the year 2007.<sup>3</sup> In order to make information consistent with the distributional analysis (January 2009), we use a static ageing technique which allows us to control for changes in global structural variables as well as income adjustments that differentiate by income components (see Gupta and Kapur, 2000). We restrict the sample to the same industries we employ in the LIAB, but include the unemployed. On the whole, this gives us 5; 532 households and 9; 218 persons. To calculate net incomes and fiscal effects, we link the data to the tax and benefit simulation model of the Institute for the Study of Labor, IZA $\Psi$ MOD, which incorporates all important features of the German tax and transfer system (see Peichl *et al.*, 2010).

#### 3.2. Labor Demand Model

16. We estimate a structural labor demand model on the LIAB data. For our purposes, it is essential to adopt a micro rather than a macro approach mainly for two reasons. Firstly, the explicit goal of our contribution is to assess the consequences of output changes on the demand for narrowly de.ned groups of workers. This implies that we have to account for substitutions patterns between different labor inputs at the .rm level. Secondly, macro models on labor demand produce unbiased results only under quite restrictive assumptions with regard to employment adjustments (see Bresson *et al.*, 1992).

17. Following standard practice, we adopt the dual approach by assuming a constant output, specifying a cost function and using Shephard.s lemma to derive the labor demand functions (Hamermesh, 1986, 1993 and Bond and Van Reenen, 2007). We opt for a Generalized Leontief specification as proposed by Diewert (1971), which is a linear second-order approximation to any arbitrary cost function. Importantly, it does not restrict the substitution elasticities of input factors. We follow the concrete specification by Diewert and Wales (1987) and take a short-term perspective, assuming capital to be fixed (or perfectly separable from labor inputs). We also allow for non-constant returns to scale, which is important in the context of our study, since the output elasticities are not restricted to equal unity.

18. For a given firm, there are i = 1, ...I labor inputs corresponding to the cells we define below. We ignore .rm and time indices to clarify notations. We write C, the short-term labor costs of a firm, as follows:

$$C = \sum_{i} \alpha_{i} w_{i} + \sum_{i} \sum_{j} \alpha_{ij} w_{j}^{0.5} w_{j}^{0.5} Y + \sum_{i} (\beta_{YYi} w_{i}) Y^{2}$$

with Y and wi the firm-specific output and the wage of labor group i, respectively. The symmetry condition  $_{ij} = _{ji}$ , 8i; j, is the only restriction imposed on the coefficients. Differentiating C with respect to wages wi yields the factor demands Xi or, dividing by Y, the input-output ratio:

$$X_i/Y = \alpha_{ii} + \sum_{j \neq i} \alpha_{ij} \left(\frac{w_j}{w_i}\right)^{0.5} + \alpha_i \frac{1}{Y} + \beta_{YYi} Y$$

which is the basis of our labor demand estimation. Since we are analyzing the comparativestatic effect of output shocks, our main measure of interest is the output elasticity of input (labor) demand, which is written as:

$$\epsilon_{iY} = \frac{\partial X_i}{\partial Y} \frac{Y}{X_i} = 1 - \frac{\alpha_i}{X_i}$$

<sup>&</sup>lt;sup>3</sup> As explained in the introduction, it is precisely the lack of rapid microdata production that justifies our approach. For instance, the GSOEP data for year 2008 are becoming available at the end of 2010.

#### 3.3. Estimation

19 The detailed administrative data allow us to distinguish I = 12 labor inputs per industry. We differentiate between two skill/education levels, three age groups and two categories of employment contract. Skilled workers hold a university, polytechnical, or college degree or have completed vocational training. Age groups are de.ned as 15-29 (young), 30-54 (middle-age) and 55-64 (old). We differentiate between full-time workers and a "non-standard" employment type category comprising both part-timers and irregular employment (short-term employment, temporary workers and those in marginal employment referred to as "Mini/Midijob" in Germany). We estimate input-output ratios separately for the five industries (manufacturing, construction, trade and communications, services and financial services) which gives 5 12 = 60 different cells that can be used for the distributional analysis. There is clearly no complete congruence, and possibly a trade-off, between the definition of labor inputs used for the purpose of labor demand estimation on one hand, and a disaggregated cell definition for precise distributional analyses on the other. We feel that the choice made here presents a reasonable balance. In particular, skill and age/experience groups constitute different types of productive factors for firms but also correspond to groups exposed to different risks of unemployment or working-time adjustments during a labor-market downturn. One may wish more disaggregation for the distributional analysis (e.g., gender, migrants) but this would be more difficult to justify in terms of labor-input differentiation.

20. We specify our labor demand model with respect to total working hours exploiting establishment level working time information. To the best of our knowledge such a micro level hours specification is unique. Most of the related studies estimating demand systems rely on the textbook head-count specification. A few other papers specify their model in terms of hours by appending an hours-worked measure to the data (see Hamermesh, 1993). Due to a lack of firm-level information such working-hours measures normally rely on some sub-aggregate averages (in most cases on the industry level) at a given point in time (see Freier and Steiner, 2009 for a recent example). Our approach improves on this in several ways. First, we know actual full-time working hours, as well as the number of full-time and part-time workers, at the establishment level directly from LIAB. For full-time workers, we therefore have all the information at a disaggregated level from GSOEP. More specifically, we derive ratios of full-time and part-time working hours for each age/skill/employment type/industry/year cell in GSOEP. We then apply these ratios to the LIAB data to obtain part-time working hours. Using this approach, we construct a finely grained working hours distribution across worker groups in each establishment.

21. The model is estimated by adding disturbance terms  $\varepsilon_i$  to the input-output ratios (2) for the i = 1, ...,12 inputs in each industry. The disturbance vector ( $\varepsilon_1, ..., \varepsilon_{12}$ ) is assumed to be multivariate and normally distributed with mean vector zero and constant covariance matrix. The system of 12 equations per industry is estimated using Seemingly Unrelated Regression (SUR) proposed by Zellner (1962). SUR first employs equation-by-equation OLS to obtain the covariance matrix of the error terms,  $\Omega$ , then a Feasible Generalized Least Squares estimation on the full system, conditional on  $\Omega$  is conducted. Thus, SUR allows error terms to be contemporaneously correlated across regressions and is more efficient than separate OLS estimations.

22. Due to the complexity of the model and to save on space, we do not present the detailed estimates but simply focus on goodness-of-fit measures (and the predictive power of the model) and on output elasticities of labor demand, the important results for our purpose.<sup>4</sup> Table 8 in the appendix presents standard goodness-of-fit measures by industry for all demand equations. The table shows that the model fit as indicated by the adjusted r-squared and chi-squared values is reasonably good, especially when taking

<sup>&</sup>lt;sup>4</sup> Detailed regression results are available from the authors on request.

into account that the equation system is quite complex and that 66 cross-equations constraints on the coefficients are imposed.<sup>5</sup> Only the fit of the model for the financial sector is less than satisfactory, which is most probably due to challenges in measuring output in a manner consistent with other industries, as well as the relatively small number of observations.<sup>6</sup> In addition, it is useful to check the predictive power of the model. In Figure 2, we plot yearly relative changes in total hours worked as reported in the LIAB data against changes as predicted by the model for each industry over 1996-2007. Predicted changes in working hours are derived by multiplying the industries output elasticities by the industry-specific aggregate output change. With the exception of the financial sector, the graphs show that predictions appear quite accurate. This is reassuring regarding the estimated model and provides some confidence that using employment reaction to output changes over the entire period results in good approximations of employment changes in specific time periods.

23. Table 1 presents output elasticities of labor demand. For readability, we present average elasticities for broader input groups in this table. Complete results for all 60 cells are reported in Table 9 in the appendix. All group elasticities are positive as required by theory. The average output elasticity across all cells is 0:64, which is well in line with other studies determining employment reactions to output shocks (normally output elasticities lie in [0:5; 0:9], see e.g. Brechling and O.Brien (1967), Fay and Medoff(1985) or Card, 1986). The results suggest that unskilled employees are hired more quickly in a boom and fired faster during a recession across all sectors. Output elasticities of young and, especially, older workers are also above average. As expected, those on non-standard employment contracts are more likely to be affected by output changes than regular ("full-time") employees.

<sup>&</sup>lt;sup>5</sup> With I = 12 simultaneous equations, the number of constraints following the condition  $\alpha_{ij} = \alpha_{ji}$  is  $\frac{I(I-1)}{2} = 66$ .

<sup>&</sup>lt;sup>6</sup> In fact, we could not use any observations for the financial sector for the years 2006 and 2007 because the LIAB output measure changed as of 2006.

### **Figure 2: Predictive power**

Note: Actual hours from LIAB, predicted hours calculated using LIAB output data and estimated elasticities.

#### Table 1: Output elasticities

Group	Man	Con	Tra	Ser	Fin	Total
Skilled	0.57	0.45	0.79	0.62	0.94	0.59

Notes: All numbers are averages weighted by the number of total hours in the respective cells. Man = Manufacturing, Con = Construction, Tra = Transport and Communications, Ser = Services, Fin = Financial Services.

## 4. Employment and Distributional Effects

24. We now model the impact of the crisis, first on employment using the labor demand model, then on household income distribution by transposing the predicted employment effects into the GSOEP data. Our reference period for the output shock (and subsequent employment/distributional changes) is the period 2008-2009, which corresponds to the recent downturn period in Germany.

## 4.1. Output Shocks and Predicted Employment Effects

25. Results are summarized in Table 2. The top panel reports changes in official output aggregates and employment by industry over the recent crisis period. Output, as measured by value added for each industry from German national accounts, dropped in all of the shown industries. Overall, the German economy shrunk by five percent over this period. In the selected sample of industries, value added declined by even more (8 percent).<sup>7</sup> In particular, the decline in manufacturing output, a slump of 18 percent, is noteworthy.

26. Employment changes are shown in headcounts (employment levels) as well as total hours worked, accounting for adjustments along both the extensive and intensive margin. It is evident that the output shock did result in sizable labor demand effects overall. Yet, there is a considerable difference between the margins of adjustment. While changes in employment levels are minimal, total hours worked dropped substantially over a relatively short period of time, with a very large drop of about 10% in the manufacturing sector.

27. The bottom panel of Table 2 shows changes in total hours worked across industries and for different groups of workers as predicted by the labor demand model. For the prediction, we multiplied reported industry output changes with the corresponding output elasticities of labor demand in each of the 60 cells. As we have chosen a "total hours" specification, our predictions are conceptually comparable to the official changes in total working hours shown in the top part of the table. Our predictions capture the overall changes well, both quantitatively and qualitatively. Only in the Transport and Communications sector, we overestimate the labor demand reaction (possibly explained in part by stimulus spending benefiting this sector). Moreover, the table suggests that different types of workers are affected differently, with old, unskilled and non-standard workers suffering the most.

<sup>&</sup>lt;sup>7</sup> The difference is mostly due to the public sector, where value added actually increased during the crisis period.

Table 2: Output Shocks and Actual vs. Predicted Hours Adjustments

Sources: Value Added from German National Accounts (constant prices, chain-linked index, 2000=100). Official employment statistics from the Institute for Employment Research. Predictions are based on LIAB.

Notes: Man = Manufacturing, Con = Construction, Tra = Transport and Communications, Ser = Services, Fin = Financial Services.

#### 4.2. Cell Identification and Shock Scenarios

28. We now feed the predicted employment shocks for each cell into the GSOEP, a representative micro dataset often used for distributional analyses. The GSOEP is informationally rich and allows us to differentiate by skill, age, employment group and industry, just as we did in the linked employer-employee data. Table 3 provides an overview of selected worker characteristics for both the LIAB and GSOEP datasets. The table reveals that, although general socio-demographic characteristics such as gender or nationality differ the two datasets compare well as far as the dimensions of our cells are concerned. In particular, the age and employment-type distributions are almost identical.

29. The labor-demand model is specified in terms of total hours and hence accounts for adjustments at both the extensive and intensive margin. Yet, the model cannot predict which margin is used by a particular firm or sector. Thus, we must suggest concrete scenarios of labor market adjustments to translate total hour changes into income changes at the cell level. Since actual labor-input adjustments during the 2008-2009 crisis were mainly along the intensive margin in Germany, we suggest a first scenario where adjustments exclusively materialize as a change in worked hours (e.g., a switch from full-time to part-time employment). We simply change working hours proportionally in line with the total change in labor demand at the cell level, holding employment levels constant.

Table 3: Worker characteristics, wave 2007

Source: Own calculations using LIAB and GSOEP.

30. In a second polar case, we suggest a scenario where the same total hours adjustments only occur at the extensive margin through layoffs. That is, adjustments consist in changes in employment rates at the cell level: If the predicted change in labor demand for a given cell is -X%, we randomly draw X% of workers within the GSOEP cell and make them unemployed. This second scenario corresponds more to the adjustment pattern that occurred in the United States

31. We feel that these two scenarios provide interesting counterfactuals for the distributional and fiscal impact of the labor-market downturn, which highlight the role of the adjustment margin in shaping distributional outcomes and correspond reasonably well to the adjustment patterns observed in Germany and the United States. It is likely, however, that the differences between the distributional effects of our

stylised scenarios provide upper bound estimates. First, adjustments will generally take place along both the intensive and the extensive margins. On a more technical level, we abstract from the facts that working-hours reductions will not be uniform within each cell and that unemployment risks within cells will not be evenly distributed. However, in the context of our distributional analysis, the random draw will have no noticeable impact as cell definitions are already disaggregated.<sup>8</sup>

### 4.3. Distributional and Fiscal Impacts

32. The distributional analysis is based on GSOEP data before and after the different employment shocks. We denote by "0" the pre-crisis (baseline) situation, by "1" the post-crisis scenario resulting from adjustments along the intensive margin only and by "2" the post-crisis scenario resulting from extensive-margin adjustments. Income distribution measures are based on household total income equivalized using the modified OECD scale. Capturing the household context (family size and composition) is of course a principal reason for performing the distributional analysis on GSOEP-type of data rather than using the worker-based LIAB directly.

33. We look at the distributions of both gross and net incomes in order to capture the cushioning effect of the tax-benefit system. We assume policy parameters as of January, 1st 2009.<sup>9</sup> Table 4 shows large working-hours changes for workers in the manufacturing industry mirroring the predicted labor-input adjustments reported in Table 2.<sup>10</sup> Gross earnings follow changes in total working hours. They are not the same, however, since working hours are shown at the individual level, whereas incomes are measured on an "equivalized" household basis and, hence, are also affected by the incomes of other family members. This is also why incomes can change for the non-employed and why relative changes in (household) earnings can exceed changes in (individual) working-hours reductions. Across industries, particularly unskilled workers are found to suffer the biggest earnings losses. Young individuals are also seeing large net income losses. Average losses are even larger than for the older age group, despite the earlier finding in Table 2 that older workers are somewhat more likely to face job loss or working-time reductions than young workers. One reason is that older workers are more likely to be living with a partner whose income partly shields them from a drop in household incomes.

34. It is striking that the net income effects are more sizable in the intensive scenario. This is because, in the intensive scenario, hours are equally reduced for everybody who is working in a specific cell. Hence, every worker in this cell suffers equal, but relatively small income losses. Tax burdens also decline for these workers, which is why income losses are smaller on a net basis than before taxes. In the extensive scenario, certain workers are laid off, resulting in a sharp drop of their gross income. On top of reduced tax burdens, a considerable part of the earnings loss tends to be offset by an entitlement to unemployment benefits. Consequently, the income cushioning effect of the tax-benefit system is larger

<sup>&</sup>lt;sup>8</sup> Any non-random modeling attempt would, in fact, run into difficulties as it would have to utilize characteristics (such as age, education) that are similar to the ones used to distinguish cells. Also note that some intermediary scenarios based on more realistic combinations of the intensive and extensive Margins could be suggested but would certainly rely on additional assumptions. We keep this work for future research.

<sup>&</sup>lt;sup>9</sup> It is important to note that net income calculations do not account for benefits paid through the short-time working programme (*Kurzarbeit*) as our data do not allow us to identify the likely recipients of these benefits. This is relevant when considering the distributional effects reported for the "intensive" scenario below. While this provides a lower-bound for the incomes of many of the workers affected by reduced working hours, recall that the large majority of working-hour reductions in 2009 (75%) were not on account of the *Kurzarbeit* system.

<sup>&</sup>lt;sup>10</sup> Note that, because the sampling frames for the GSOEP and LIAB data are different and predictions from the demand model have been applied cell-by-cell to the GSOEP, total working-hours changes and by industry do not match exactly.

than under the intensive scenario, and the difference between net and gross income changes is more sizable as a result. Note that this effects also operates for non-employed individuals, who can be sharing a household with job losers entitled to unemployment benefits.

35. Comparing changes in gross and net income gives some indication of the effectiveness of social safety nets at absorbing some of the income loss. The income of low-skilled workers is likely to be relatively close to the level of minimum-income benefits. Safety-net benefits therefore absorb a large part of their earnings losses on average resulting in large differences between gross and net earnings changes. Reflecting the EUR 400/800 ceiling on monthly earnings in the German Mini/Midijob programme, wages of many workers in the "non-standard" category are also especially low. However, these jobs are particularly attractive for second earners. Because of their higher-earning partners, they are then less likely to receive means-tested benefits when losing all or part of their own earnings.

36. Table 5 presents changes of incomes and working hours by decile groups.<sup>11</sup> Interestingly, relative net income losses in the "intensive" scenario are very similar from decile four to ten. Perhaps even more strikingly, the lowest two decile groups see the smallest net income changes, showing the effectiveness of the benefit system. A somewhat similar picture emerges if labor demand adjustments take place entirely through layoffs. Again, net income losses tend to be less severe than in the intensive scenario. This is not the case, however, for the first two decile groups. The reason is that those at the bottom of the income distribution tend to be entitled to means-tested benefits, which ensure that net incomes at the very bottom change very little in both the intensive and extensive scenarios. As a result, whether or not those affected by earnings losses are entitled to unemployment benefits makes little difference and net income changes for the two scenarios are more similar for the bottom two deciles than for middle-class households.

37. Table 6 reports a range of global distribution measures (Gini, General Entropy, inter- decile ratio), as well as absolute and relative poverty headcount (Foster-Greer-Thorbecke: FGT0) and poverty intensity (FGT1, FGT2). Consistent with the results by income deciles, overall inequality is reduced in the "intensive" scenario. The income distribution is compressed as parts of the working population suffer income losses, while the net incomes of the non-employed change less. In the "extensive" scenario, however, inequality rises as some workers are laid off while others are not affected by the crisis at all. Because the incidence of job losses is particularly high for some groups who tend to have low incomes even prior to unemployment (e.g., young and low-skilled workers), this additional unemployment yields a further widening of the income distribution. The difference between the inequality measures in the two scenarios illustrates that facilitating working-hours adjustments can play an important role in limiting the growth of income disparities during a downturn.

Table 6: Inequality and poverty measures and relative change

Source: Own calculations using GSOEP and IZA $\Psi$ MOD.

Notes: Measures are based on equivalized disposable incomes (modi.ed OECD scale) and refer to the selected sample only (working-age individuals and household members). The poverty line is set at 60% of median income (of the total population) and is either constant using the baseline median (FGT0, FGT1, FGT2), or variable using the median of each scenario (FGT0v).

38. This can also be seen when looking at poverty measures. In the intensive scenario, the share of the poor as indicated by the headcount ratio using a constant poverty line (FGT0) increases only slightly, while we see a substantial rise of more than ten percent in the extensive case. Other poverty indicators come to quantitatively similar results. But interestingly, with a variable poverty line (FGT0v), the number of poor in the intensive scenario actually goes down, since median income (and, hence, the poverty threshold) drop more strongly than incomes at the very bottom of the distribution. These results underline the importance of evaluating relative poverty measures alongside absolute changes in income levels, especially when assessing the distributional consequences of rapid economic change. Finally, we shed some light on the role of the margin of adjustment for government's budgets.

Table 7: Fiscal effect											
	Intensive		Extensive								
Changes	in billion euros	in %	in billion euros	in %							
Tax revenue	-5.6	-4.2	-3.0	-2.3							
Social insurance contributions	-5.4	-3.2	-6.3	-3.8							
Benefit payments	-1.0	1.1	-5.3	5.9							
Total budget effect	-11.9	-5.7	-14.6	-7.0							

Source: Own calculations using GSOEP and IZA  $\Psi MOD.$ 

Notes: percentage changes refer to each category (ex: tax revenue goes down by 4.2% in intensive scenario)

39. Table 7 shows the fiscal effects of the two scenarios relative to the baseline case, i.e. the German tax benefit system as of January, 1st 2009 without any crisis-related employment changes. As one would

expect, both scenarios result in a highly negative effect on the government budget. Tax revenue and social insurance contributions (SIC) decrease as labor earnings drop for those employees affected by the crisis. It is interesting to note the differences between the two scenarios in terms of taxes and SIC. In the intensive case, the proportional reduction in combination with the progressive income taxation and regressive SIC yields higher relative tax revenue reductions. In the extensive scenario, employment reductions are highest in the middle part of the income distribution (cf. Table 5), where SIC payments are higher than tax liabilities. As the highly progressive German income tax is concentrated at the top (with the top ten percent paying more than 55 percent of the income tax revenue), the reduction in tax revenue is relatively lower than the decrease in SIC. Due to higher benefit expenditures, the fiscal consequences of the extensive scenario are, however, substantially more severe (benefit payments increase by 6%). In total, the government's budget is decreasing by 7 percent in this case. This yields an eventual shortfall which is approximately 3 billion euros higher than in the intensive scenario, given our considered population sample.<sup>12</sup>

#### 5. Conclusion

40. In this paper we propose a new method to gauge the first-round labor-market, distributional and fiscal implications of large output changes. The method is based on a disaggregated labor-demand model motivated by the fact that labor demand changes are the principal driving factor of household income losses in the early phase of a labor-market downturn. The labor-demand adjustments are then combined with detailed household microdata to translate changes in individual earnings into income changes at the household level. This approach can help policymakers to design policy responses to economic downturns in the absence of reliable real-time microdata.

41. We apply the method to investigate the impact of the 2008-2009 downturn in Germany. Our results show that German low-skilled and non-standard workers faced above-average risks of earnings losses, in particular if they worked in the manufacturing sector where output reductions were very large. When looking at the resulting income losses, it turns out, however, that automatic stabilization by the taxbenefit system is effective in cushioning a significant share of the gross-income losses, especially among low-income groups (cf. also Dolls *et al.*, 2010).

42. The choice of Germany is interesting as German employment levels and unemployment rates were unusually stable in the face of a large and rapid drop in economic output, while average hours worked per employee did decline significantly. This reflects in part Germany's primary policy response to the crisis facilitating necessary labor-cost adjustments via working-hours reductions rather than layoffs. To shed light on the role of different margins of adjustment on distributional and fiscal implications of the downturn, our first scenario assumes that all employment adjustments take place via such working-hour reductions. As a contrasting scenario, we have also explored a polar situation closer to the US experience, where adjustments of employment levels were far greater. Our results show that, while a strategy to promote working-hour adjustments through work-sharing and other measures cannot prevent significant income losses, it can be highly effective at avoiding very large increases in income poverty. Calculations for Germany also show that intensive-margin adjustments are less costly for the government budget.

43. Our empirical approach has several limitations which are left for further research. Our estimates do not explicitly account for the German short-term working scheme. While participation in the scheme has been shown to be costly for firms (Bach and Spitznagel, 2009), it is likely that, as a de facto subsidy to

<sup>&</sup>lt;sup>12</sup> In a back-of-the-envelope calculation one could argue that the German short-term working scheme was an efficient investment for the initial phase of the crisis - costing a similar amount (3 billion euros per year), encouraging reductions in total working hours and thus keeping many employees in the workforce.

firms, it played a role in firms' decisions on the margin of adjustment.<sup>13</sup> Secondly and more generally, the approach in this paper has utilized recent historical data to make inferences about the effects of the current labor-market downturn. The demand model provides an interesting "average" approximation of short-term effects of output shocks. Yet institutional changes over recent years may have affected the demand for different groups of workers in complicated ways, and the policies put in place during the crisis had their own specific effects. Hence an important but challenging improvement would consist in explicitly modeling policy institutions in the labor demand estimation. Finally, an obvious limitation is the short-term horizon adopted here going along with the assumption of constant wage levels as well as the usual constant-capital assumption in labor-demand models. Although it would be worthwhile to model wage variations by interacting labor demand and supply iteratively in order to attain equilibrium(see e.g. Peichl and Siegloch, 2010), we have argued that this assumption is not too restrictive in the context of our study as wage reductions were not a primary response to the labor-market downturn in Germany.

<sup>&</sup>lt;sup>13</sup> In particular, measures such as the *Kurzarbeitergeld*, which protect existing jobs, tend to reinforce employer incentives to hoard highly educated or experienced workers, while less attractive jobs may be cut more quickly. It is therefore possible that their distributional properties are less attractive than the stylized across-the-board working-time reductions considered in this paper, especially if they reduce labor-market dynamics, making labor-market re-entry more difficult for laid-off workers. It would be interesting to investigate the incidence of short-time working schemes more closely once the required data become available.
